## Abstract

TOPEX/Poseidon sea surface height anomalies (SSHAs), Sea-viewing Wide Field-of-view Sensor (SeaWiFS) L3 chlorophyll *a* (chl-*a*) concentration, and primary production were examined to determine the relationship between an eddy field and primary productivity along the shelf edge in the southeastern Bering Sea. Primary production was calculated from SeaWiFS chl-*a*, photosynthetically active radiation (PAR), and AVHRR sea surface temperature (SST) data using the vertically generalized production model (VGPM).

A time–latitude plot of SSHAs, which was derived from TOPEX/Poseidon ground track D-79 along the shelf edge, described the northwestward propagation of positive SSHAs (indicating an anticyclonic eddy) and negative SSHAs (indicating a cyclonic eddy) staying near Zhemchug Canyon or over the deep basin). There were increases in the variability of the SSHA field and the speed of eddy propagation during 2000 along the shelf edge. Time–latitude plots of SeaWiFS chl-*a* exhibited relatively high chl-*a* (over  $1.0 \text{ mg m}^{-3}$ ) along the shelf edge for 2–3 months in the summer of 1999, when there was low eddy activity, and for about 6 months in 2000, when there was an eddy-rich environment. The same pattern of chl-*a* appeared in time–latitude plots of primary production. Monthly averaged primary production along the shelf edge was 20.88, 18.37, and  $24.04 \text{ g C m}^{-2} \text{ month}^{-1}$  in 1998, 1999, and 2000, respectively. Primary production decreased from about  $28 \text{ g C m}^{-2} \text{ month}^{-1}$  (June) to about  $18 \text{ g C m}^{-2} \text{ month}^{-1}$  (July) in 1999; however, about  $25 \text{ g C m}^{-2} \text{ month}^{-1}$  of primary production was maintained from June to September in 2000. These results indicate a positive correlation between the variability in the Bering Slope Current (BSC) eddy field and primary production along the Bering Sea shelf edge. An increase in the BSC transport and the eddy field fluctuation contributed to the vertical nutrient supply to the subsurface layer and shelf–slope exchange, thereby maintaining high primary productivity along the shelf edge of the southeastern Bering Sea in 2000.

## 34 1. Introduction

36 The Bering Sea shelf break is a part of the  
 37 boundary that forms the cyclonic Bering Sea gyre  
 38 (Fig. 1). Along the shelf break, the Bering Slope  
 39 Current (BSC), the eastern boundary current of Bering  
 40 Sea gyre, flows at about  $5\text{--}15\text{ cm s}^{-1}$  northwestward  
 41 and commonly forms mesoscale eddies (Kinder et al.,  
 42 1975, 1980; Schumacher and Reed, 1992; Stabeno  
 43 and Reed, 1994; Schumacher and Stabeno, 1994;  
 44 Cokelet and Stabeno, 1997; Mizobata et al., 2002).  
 45 The structures of the BSC show either a highly  
 46 variable flow interspersed with eddies, meanders,  
 47 and instabilities, or a regular northwestward-flowing  
 48 current (Stabeno et al., 1999). These eddies are  
 49 ubiquitous features in the oceanic region of the Bering  
 50 Sea (Schumacher and Stabeno, 1994; Napp et al.,  
 51 2000) and can be detected by satellite altimeter

throughout the year (Okkonen, 1993, 2001). Recently,  
 several studies have shown there is an onshelf flow  
 associated with mesoscale eddies from the oceanic  
 region to the shelf region (Schumacher and Reed,  
 1992; Schumacher and Stabeno, 1994; Stabeno and  
 Meurs, 1999). These onshelf flow and eddy move-  
 ment indicate that exchange occurs between the shelf  
 and the slope. This exchange is thought to be an  
 important process for maintaining the high productiv-  
 ity of the “Green Belt” (Springer et al., 1996; Stabeno  
 et al., 1999; McRoy et al., 2001).

The biological, chemical, and physical structures  
 of Bering Sea eddies have already been observed  
 (Sapozhnikov, 1993; Cokelet and Stabeno, 1997;  
 Mizobata et al., 2002) and the effects of these eddies  
 on nitrogen and phytoplankton distributions have  
 been described. Rising isopycnals indicate that nu-  
 trient-rich water is upwelled to the euphotic zone,

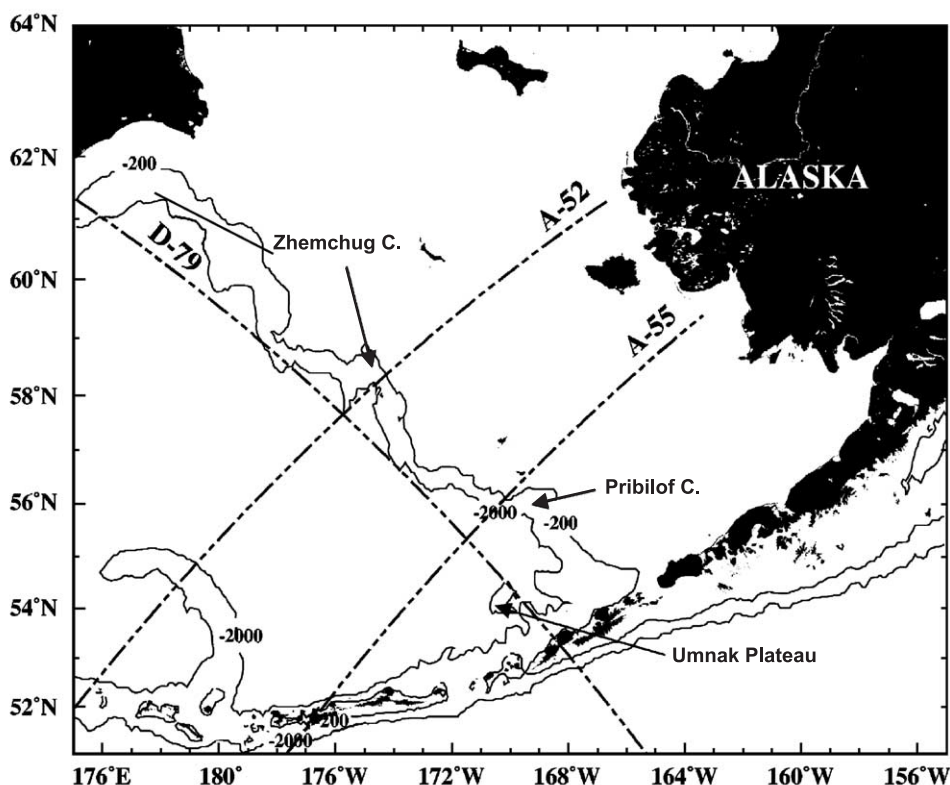

Fig. 1. The Bering Sea shelf edge shown by the 200- and 2000-m isobaths and TOPEX/Poseidon ground tracks D-79, A-52, and A-55 (dotted line) are shown. Complex shelf edge features includes Zhemchug Canyon and Pribilof Canyon.

70 leading to relatively high chlorophyll *a* (chl-*a*) con-  
 71 centrations ( $>1.0 \text{ mg m}^{-3}$ ) at the center of cyclonic  
 72 eddy and around the periphery of the anticyclonic  
 73 eddy (Mizobata et al., 2002). The downwelling of  
 74 the surface warm water with low nutrients destroyed  
 75 a cold layer resulting from winter convection at the  
 76 center of the anticyclonic eddy. These eddies have  
 77 been shown to influence both lower and higher  
 78 trophic levels, especially walleye pollock *Theragra*  
 79 *chalcogramma* (Incze et al., 1991; Schumacher and  
 80 Stabeno, 1994; Schumacher et al., 1993; Bograd et  
 81 al., 1994; Napp et al., 2000). In the Bering Sea  
 82 basin, data from satellite-tracked drifters indicate that  
 83 high concentrations of larval pollock are associated  
 84 with eddies (Schumacher and Stabeno, 1994). De-  
 85 spite the importance of these eddies, their horizontal  
 86 distribution and motion in the oceanic region are  
 87 still unknown. In this study, we analyzed satellite  
 88 altimeter and chl-*a* data to understand the relation-  
 89 ship between the Bering Slope Current eddy field  
 90 and the primary production along the Bering Sea  
 91 shelf edge.

## 92 2. Data and methods

### 93 2.1. TOPEX/Poseidon sea surface height anomaly 94 (SSHA)

96 The Bering Slope Current eddy field can be de-  
 97 scribed using TOPEX/Poseidon SSHAs (Okkonen,  
 98 2001). In this study, SSHAs were calculated from  
 99 TOPEX/Poseidon Merged Geophysical Data Record  
 100 Generation-B from January 1998 to December 2000  
 101 (cycle 195–305) distributed by the NASA/Jet Propul-  
 102 sion Laboratory PO.DAAC (Benada, 1997). We  
 103 examined TOPEX/Poseidon ground track D-79  
 104 ( $54^\circ\text{N}$ – $60.5^\circ\text{N}$ ), A-52 ( $180^\circ\text{E}$ – $174^\circ\text{W}$ ), and A-55  
 105 ( $175^\circ\text{W}$ – $170^\circ\text{W}$ ) SSHAs to reveal the variability and  
 106 movement of the Bering Slope Current eddy field  
 107 (Fig. 1). Then the root mean square (RMS) of SSHAs  
 108 along D-79 was estimated to illustrate eddy activity  
 109 along the shelf edge.

### 110 2.2. SeaWiFS sea surface chl-*a*

112 Sea surface chl-*a* ( $\text{mg m}^{-3}$ ) obtained by satellite  
 113 ocean color sensors often showed mesoscale fea-

114 tures (Fig. 2). Monthly Sea-viewing Wide Field-of-  
 115 view Sensor (SeaWiFS) Level 3 chl-*a* standard  
 116 mapped images with 9 km of spatial resolution  
 117 (OC4V4; January 1998–December 2000) were pro-  
 118 cessed for comparison with the SSHAs data. After  
 119 Mercator mapping using the SeaWiFS Data Analy-  
 120 sis System (SeaDAS) distributed by NASA Goddard  
 121 Space Flight Center,  $5 \times 5$  pixel ( $45 \times 45 \text{ km}$ )  
 122 averaged chl-*a* values were extracted directly under  
 123 the TOPEX/Poseidon orbital ground track D-79 to  
 124 exclude cloud effects caused by the substantial  
 125 cloud cover in the Bering Sea. In this study, we  
 126 used this averaged value to focus on the effect of the  
 127 mesoscale eddies (diameter =  $50$ – $200 \text{ km}$ ). Smaller  
 128 eddies (diameter  $< 50 \text{ km}$ ) were excluded from the  
 129 analyses.

### 130 2.3. Primary production

132 Primary Production ( $\text{PP}_{\text{eu}}$ ) was calculated from  
 133 SeaWiFS Level 3 chl-*a*, SeaWiFS Level 3 photosyn-  
 134 thetically active radiation (PAR;  $\text{mol quanta m}^{-2}$ ),  
 135 and NOAA/AVHRR Oceans Pathfinder sea surface  
 136 temperature (SST) data (October 1997–May 2001)  
 137 using the vertically generalized production model  
 138 (VGPM) developed by Behrenfeld and Falkowski  
 139 (1997) (hereafter referred to as BF97) and improved  
 140 by Kameda and Ishizaka (2002) (hereafter referred to  
 141 as KI02). Both SeaWiFS Level 3 PAR and AVHRR  
 142 SST have a 9-km resolution, as does SeaWiFS Level 3  
 143 chl-*a*. The VGPM can estimate the  $\text{PP}_{\text{eu}}$  ( $\text{mg C m}^{-2}$   
 144  $\text{day}^{-1}$ ) derived from the relationship between surface  
 145 chlorophyll and depth-integrated primary production.  
 146 A detailed description of the VGPM is presented in  
 147 BF97, so a brief overview is given here. The main  
 148 equation is expressed as:

$$\text{PP}_{\text{eu}} = \text{Chl}_{\text{surf}} Z_{\text{eu}} P_{\text{opt}}^{\text{B}} \text{DL} \left[ 0.66125 \frac{E_0}{E_0 + 4.1} \right] \quad (1)$$

149 where  $\text{Chl}_{\text{surf}}$  is the SeaWiFS chl-*a* described previ-  
 150 ously, DL is daylength (or photoperiod) in decimal  
 151 hours,  $Z_{\text{eu}}$  is the physical depth of the euphotic zone  
 152 defined as the penetration depth of 1% of surface  
 153 irradiance and calculated from  $\text{Chl}_{\text{surf}}$ , and  $E_0$  is  
 154

Fig. 2. SeaWiFS chl-*a* composite image of the Bering Sea basin in May and June 2001. In the shelf region and deep basin, chl-*a* concentrations were low. Along the shelf edge (white arrow), however, there were high chl-*a* ring (54°N, 167°W) and bands associated with many mesoscale features, indicating the “Green Belt.”

155 SeaWiFS Level 3 PAR. The bracketed equation is  
 156 called the  $F$  function, which is the relative fraction of  
 157 potential photosynthesis lost within the euphotic zone  
 158 due to light limitation.

159  $P_{\text{opt}}^{\text{B}}$  in Eq. (1) is the optimal rate of daily carbon  
 160 fixation within the water column [ $\text{mg C (mg Chl)}^{-1}$   
 161  $\text{hour}^{-1}$ ]. BF97 described  $P_{\text{opt}}^{\text{B}}$  as:

$$P_{\text{opt}}^{\text{B}} = \begin{cases} 1.13 & \text{if } T < -1.0 \\ 4.00 & \text{if } T > 28.5 \\ P_{\text{opt}}^{\text{B}'} & \text{otherwise} \end{cases} \quad (2)$$

$$P_{\text{opt}}^{\text{B}'} = 1.2956 + 2.749 \times 10^{-1}T + 6.17 \times 10^{-2}T^2 - 2.05 \times 10^{-2}T^3 + 2.462 \times 10^{-3}T^4 - 1.348 \times 10^{-4}T^5 + 3.4132 \times 10^{-6}T^6 - 3.27 \times 10^{-8}T^7 \quad (3)$$

where  $T$  is SST ( $^{\circ}\text{C}$ ). KI02 showed that the BF97  
 VGPM with its high variance of  $P_{\text{opt}}^{\text{B}}$  tends to overes-  
 timate or underestimate  $\text{PP}_{\text{eu}}$  at high or low chl-*a*  
 areas in the North Pacific and Japan Sea, respectively.  
 Moreover, KI02 found a relationship among  $P_{\text{opt}}^{\text{B}}$ ,  
 SST, and  $\text{Chl}_{\text{tot}}$  from their in situ database in the  
 North Pacific. Several studies have shown that various  
 sizes and species of phytoplankton occur at the Bering

173 Sea shelf edge and in the Bering Sea Basin, including  
 174 microphytoplankton, nanophytoplankton, and pico-  
 175 phytoplankton (Sukahanova et al., 1999; Shiomoto  
 176 et al., 2002; Liu et al., 2002). Then KI02 suggested a  
 177 new  $P_{\text{opt}}^{\text{B}}$  in consideration of a dual phytoplankton  
 178 (large and small size) community as:

$$P_{\text{opt}}^{\text{B}} = (0.071T - 3.2 \times 10^{-3}T^2 + 3.0 \times 10^{-5}T^3) / \text{Chl}_{\text{surf}} + (1.0 + 0.17T - 2.5 \times 10^{-3}T^2 - 8.0 \times 10^{-5}T^3) \quad (4)$$

180 where  $T$  is the NOAA/AVHRR Pathfinder SST data  
 181 described before. In this study, we used the VGPM  
 182 with the KI02  $P_{\text{opt}}^{\text{B}}$  to estimate the primary production  
 183 along the shelf edge.

### 184 3. Results

#### 185 3.1. Bering Slope Current eddy field in the summer of 186 1998–2000

188 The TOPEX/Poseidon orbital ground track D-79  
 189 lies along the shelf edge of the Bering Sea (Fig. 1).  
 190 Following Okkonen (2001), time–latitude plots of  
 191 SSHAs (Fig. 3a) were used in this study. Fig. 3a  
 192 shows the characteristics of SSHA variability along  
 193 and across the shelf edge. The distribution of positive  
 194 and negative SSHAs is roughly separated from 54°N  
 195 to 56°N and from 56.5°N to 60.5°N in 1998 (before  
 196 cycle 230). After cycle 230, however, this separation  
 197 was unclear. Separation of the BSC has been inferred  
 198 from drifter trajectories and altimeter analyses (Sta-  
 199 beno and Reed, 1994; Okkonen, 2001) and is proba-  
 200 bly due to the tongue-like shape of the shelf break  
 201 between Zhemchug Canyon and Pribilof Canyon.  
 202 While most of the positive SSHAs, which indicate  
 203 anticyclonic eddies, propagated northwestwardly  
 204 along the shelf edge over Umnak Plateau from  
 205 55°N to 56°N, the negative SSHAs, which indicate  
 206 cyclonic eddies, tended to remain over the Umnak  
 207 Plateau and near Zhemchug Canyon and did not  
 208 move. Positive SSHAs in 1998 and 1999 continued  
 209 for longer periods (about 5–6 months) than in 2000  
 210 (about 2–4 months). The averaged velocity of eddy  
 211 propagation along D-79 was 1.40 cm s<sup>-1</sup> in 1998 and

0.79 cm s<sup>-1</sup> in 1999 with a standard error of 0.36 and  
 0.43 cm s<sup>-1</sup>, respectively. In 2000, however, this  
 velocity was 2.26 cm s<sup>-1</sup> with a standard error of  
 0.46 cm s<sup>-1</sup>. The D-79 SSHAs RMS had high  
 (RMS=60–200 mm) and low (RMS=20–60 mm)  
 variability in the summers of 1998 and 1999, respec-  
 tively (Fig. 3b). Beginning in January 2000, this  
 variability shifted from a relatively stable mode to  
 an unstable mode, and the gradient of positive SSHAs  
 propagation became steep.

The ground tracks of A-52 and A-55 lie across the  
 continental slope around Zhemchug Canyon and near  
 the Pribilof Islands, respectively (Fig. 1). Time–lon-  
 gitude plots of the SSHAs show an offshore propa-  
 gation of both anticyclonic and cyclonic eddies  
 previously described by Okkonen (2001) or retention  
 in the vicinity of continental slope, but there is little  
 indication of SSHAs or eddies moved onto the shelf  
 (Fig. 4a and b).

#### 3.2. Chl-*a* concentration and primary production along the Green Belt

We estimated chl-*a* and primary production direct-  
 ly under TOPEX/Poseidon ground track D-79 and  
 then compared these biological datasets to the eddy  
 field derived from the TOPEX/Poseidon SSHAs.  
 Time–latitude plots of chl-*a* and primary production  
 are shown in Fig. 5a and b. No SeaWiFS chl-*a* data  
 were obtained from 59.5°N to 60.5°N due to the  
 cloud cover. The distribution and duration of relative-  
 ly high chl-*a* (>1.0 mg m<sup>-3</sup>) and primary production  
 (20 g C m<sup>-2</sup> month<sup>-1</sup>) fluctuated along the shelf  
 edge from April to October each year. High chl-*a*  
 concentrations, indicative of the spring bloom along  
 the shelf edge, were observed in May 1998, June  
 1999, and June 2000. However, it is notable that chl-*a*  
 and primary production from 55.5°N to 59.5°N  
 continued only 2–3 months in the summer of 1999  
 when low eddy activity was described in previous  
 altimeter analyses. Conversely, high chl-*a* and prima-  
 ry production persisted about 6 months after the  
 spring bloom in 2000. Over the Umnak Plateau, from  
 54°N to 55.5°N, relatively high chl-*a* and primary  
 production were maintained for 4–6 months in 1998,  
 1999, and 2000.

Averaged primary production along the shelf edge  
 is well reflected in the fluctuation of the productivity

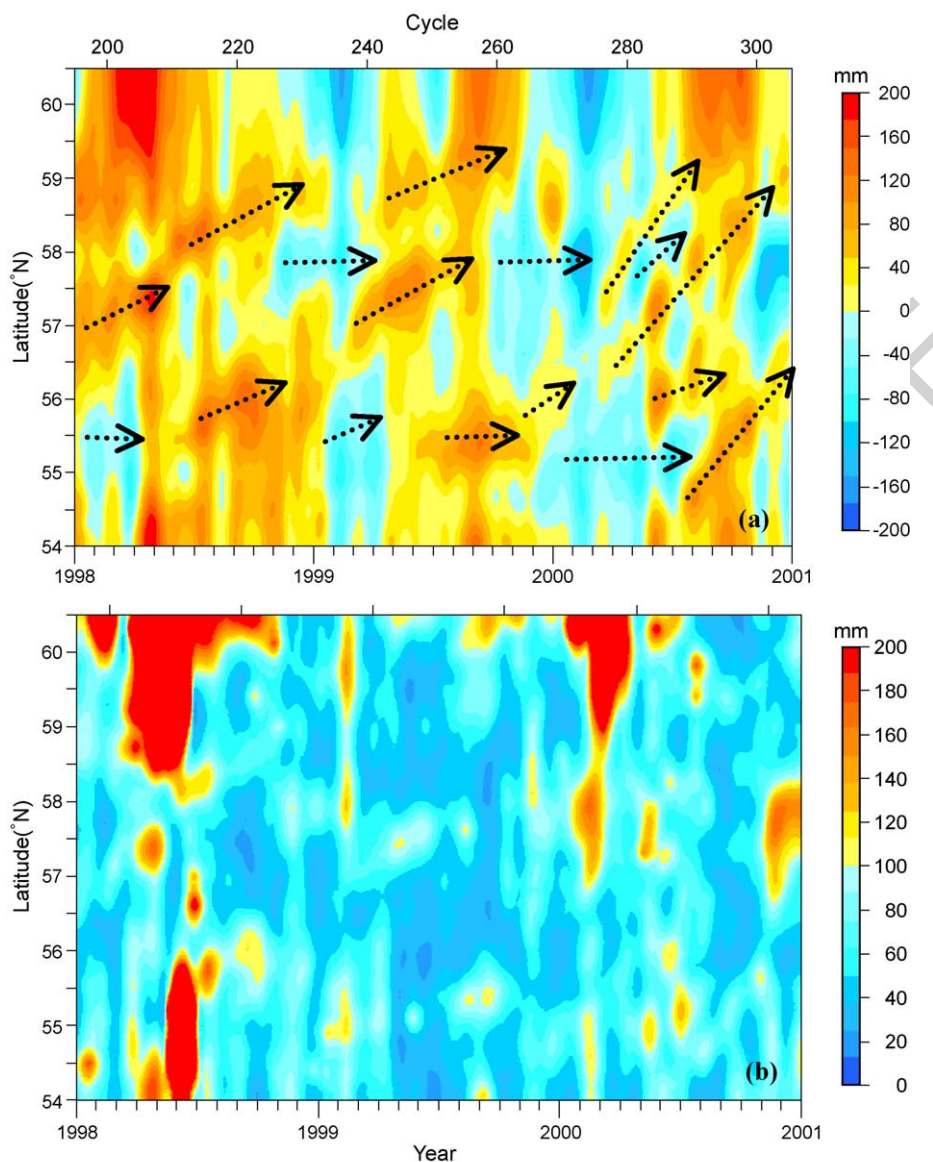

Fig. 3. Time–latitude plot of (a) TOPEX/Poseidon D-79 SSHAs and (b) SSHAs root mean square. Arrows show the direction of eddy propagation.

259 (Fig. 6). Averaged primary production along the shelf  
 260 edge decreased from about  $28 \text{ g C m}^{-2} \text{ month}^{-1}$  in  
 261 June to about  $18 \text{ g C m}^{-2} \text{ month}^{-1}$  in July of 1999.  
 262 In 2000, however, more than  $25 \text{ g C m}^{-2} \text{ month}^{-1}$  of  
 263 primary production was maintained from June to  
 264 September. Monthly averaged primary production  
 265 along the shelf edge was  $20.88 \text{ g C m}^{-2} \text{ month}^{-1}$   
 266 in 1998,  $18.37 \text{ g C m}^{-2} \text{ month}^{-1}$  in 1999, and  $24.04$

$\text{g C m}^{-2} \text{ month}^{-1}$  in 2000 with a standard error of 267  
 3.48, 3.00, and  $3.49 \text{ g C m}^{-2} \text{ month}^{-1}$ , respectively. 268

#### 4. Discussion 269

Isopleths of SSHAs described the difference in 270  
 behavior between cyclonic eddies and anticyclonic 271

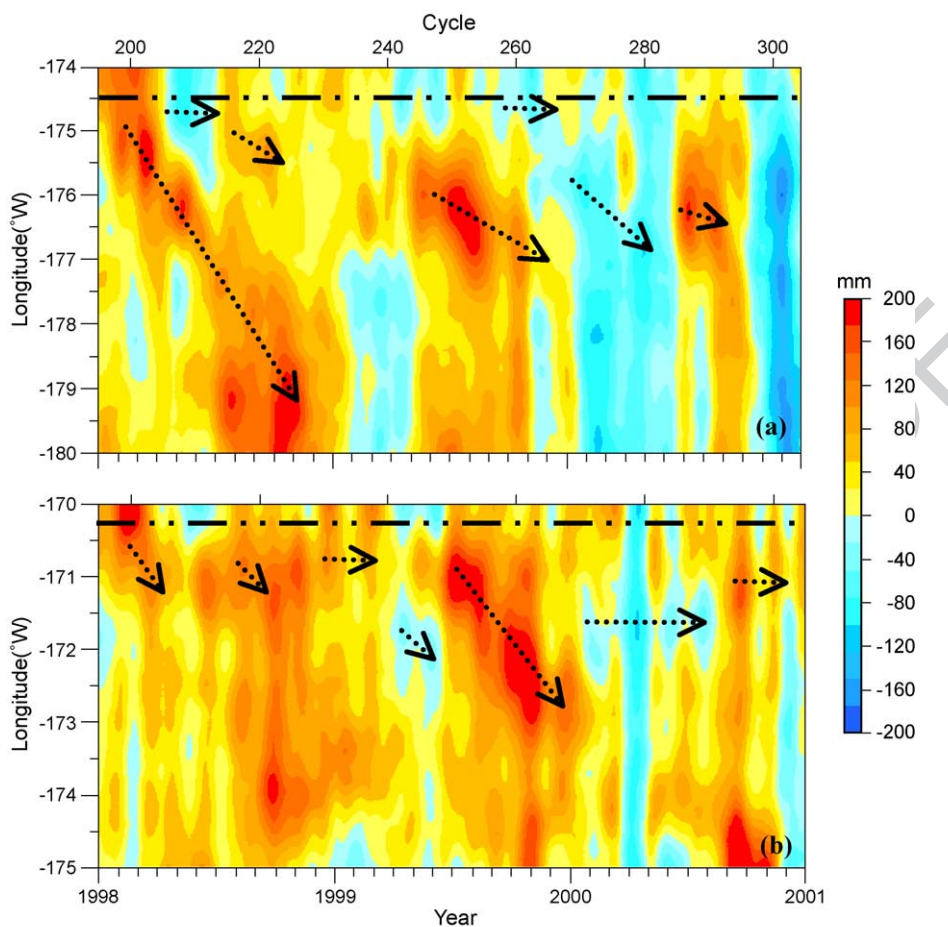

Fig. 4. Time–longitude plot of SSHAs using TOPEX/Poseidon ground tracks (a) A-52 and (b) A-55. Dotted line represented the shelf break at the 2000-m isobath. Arrows show the direction of eddy propagation.

272 eddies. Along the shelf edge of the Bering Sea,  
 273 TOPEX/Poseidon-positive SSHAs (anticyclonic  
 274 eddies) propagated northwestward as described in  
 275 Okkonen (2001); however, negative SSHAs (cyclonic  
 276 eddies) tended to remain around the shelf break  
 277 near Zhemchug Canyon and Pribilof Canyon. Addi-  
 278 tionally, our analysis showed the BSC eddy field  
 279 separated at  $\sim 56.5^\circ\text{N}$  before TOPEX/Poseidon  
 280 orbital cycle 230. These observations suggest that  
 281 the continental slope topography affects the BSC  
 282 eddy field (Stabeno and Reed, 1994; Okkonen,  
 283 2001). Certainly, there is another possibility that  
 284 the TOPEX/Poseidon ground track could not recog-  
 285 nize the smaller eddies ( $<25$  km) that slipped  
 286 offshore.

287 Movement of an eddy onto the shelf described by  
 288 Schumacher and Stabeno (1994) was not recognized  
 289 using TOPEX/Poseidon Ascending tracks 52 and 55  
 290 (Fig. 4a and b), but they did show that there are  
 291 onshelf flows described in previous many studies  
 292 (Schumacher and Reed, 1992; Schumacher and Sta-  
 293 beno, 1994; Stabeno and Meurs, 1999; Stabeno et al.,  
 294 1999). Shelf–Slope exchange can occur virtually  
 295 anywhere along the shelf break (Stabeno et al.,  
 296 1999) and a SeaWiFS chl-*a* image (Fig. 2) implies  
 297 that the advection by mesoscale features is important  
 298 for horizontal mixing. In short, shelf–slope exchange  
 299 occurred as a result of the advection by a “mesoscale  
 300 eddy chain” along the shelf break rather than the  
 301 onshore migration of eddies. Although Schumacher

Fig. 5. Time–latitude plot of (a) chl-*a* concentration and (b) primary production using SeaWiFS chl-*a* and NOAA/AVHRR SST data directly under the ground track of TOPEX/Poseidon D-79. Black shade indicates cloud pixels. Primary production was calculated using the advanced VGPM (Behrenfeld and Falkowski, 1997) described by Kameda and Ishizaka (2002).

302 and Reed (1992) have argued that shoreward transport  
 303 does not occur preferentially in the canyon, the hori-  
 304 zontal mixing by mesoscale eddies could cause the  
 305 capability of onshore transport of larval pollock and  
 306 the oceanic zooplankton. In the summer of 1998, chl-*a*  
 307 and primary production were relatively high (Fig. 5a  
 308 and b) when SSHA RMS were high (Fig. 3b), imply-  
 309 ing that a strong horizontal current could cause the  
 310 shelf–slope exchange. Conversely, relatively low ed-  
 311 dy activity and stable conditions such as those ob-

served in the summer of 1999 generate a relatively  
 unfertile environment. Over the Umnak Plateau, nu-  
 trient-rich water is transported along the Aleutian Arc  
 by the inflow of Alaskan Stream through Amchitka  
 Pass, Amukta Pass, and Unimak Pass (Schumacher  
 and Reed, 1992; Stabeno et al., 1999), and plays an  
 important role in maintaining the high productivity of  
 this area, which had long periods of high chl-*a* and  
 primary production around 54°N–55°N (over the  
 Umnak Plateau) even during the summer of 1999.

322 Besides horizontal mixing, cyclonic and anticy-  
 323 clonic eddies generate upwelling of nutrient-rich wa-  
 324 ter (Mizobata et al., 2002), therefore increasing the  
 325 fluctuation of the eddy field contribution to the  
 326 nitrogen transport into the euphotic zone following  
 327 relatively high chl-*a* concentrations and horizontal  
 328 mixing of low nutrient shelf water and high nutrient  
 329 oceanic water (McRoy et al., 2001). In 2000, the  
 330 eddy-rich environment along the shelf edge result  
 331 maintained relatively high chl-*a* and primary produc-  
 332 tion after the spring bloom. Generally, in the oceanic  
 333 region, prey concentrations are low and are dominated  
 334 by less preferred prey items, but mesoscale features,  
 335 when present, may contain much higher prey densi-  
 336 ties, with a larger proportion of the prey types pre-  
 337 ferred by first-feeding larvae (Napp et al., 2000).  
 338 Thus, the eddy-rich environment along the shelf break  
 339 in 2000 might have provided a preferable environment  
 340 for larval walleye pollock. However, the relationships  
 341 between eddy activity and SeaWiFS chl-*a* are not  
 342 coherent in the wintertime (TOPEX/Poseidon orbital  
 343 cycles 225–245 and 260–280, after 300). In the  
 344 winter, phytoplankton growth is light-limited rather  
 345 than nitrogen-limited at the Bering Sea shelf edge and  
 346 in the basin due to low solar insolation and strong  
 347 winter convection. Consequently, the nutrient supply  
 348 into the euphotic zone by mesoscale eddies will  
 349 contribute little to phytoplankton growth in the win-  
 350 tertime. This is the reason why chl-*a* is often not  
 351 coherent with eddy activity.

From time–latitude plots of D-79 SSHAs (Fig. 3a  
 and b), we assume that the variability of the occur-  
 rence of mesoscale eddy was due to changes in BSC  
 transport and speed. The speed of eddy propagation in  
 1998 and 1999 was slower than in 2000. This indi-  
 cates that the physical conditions along the shelf edge  
 in 1998 and 1999 were more stable and less likely to  
 generate mesoscale eddies. Especially, in 1999, our  
 analyses revealed small fluctuations in the eddy field  
 and low speed of northwestward eddy propagation,  
 indicating a decreased supply of eddy kinetic energy  
 by the BSC.

The main source of the BSC with eddies is the  
 Aleutian North Slope Current (ANSC), which flows  
 eastward along the northern side of the Aleutian  
 Islands resulting from the inflow of the Alaskan  
 Stream through Amchitka Pass and Amukta Pass  
 (Reed and Stabeno, 1999). The advection of the  
 Alaskan Stream is strongly affected by Aleutian low  
 pressure events (Hollowed and Wooster, 1992), and  
 the sea level pressure (SLP) field in the northeastern  
 North Pacific showed more intense winter Aleutian  
 lows in 2000, as opposed to 1999, implying weak  
 advection into the Alaskan Stream (not shown). Ad-  
 ditionally, local wind forcing has little effect on ocean  
 currents (Schumacher and Reed, 1992; Cokelet and  
 Stabeno, 1997), and the strong variability of inflow  
 through Amchitka Pass, Amukta Pass, and Unimak  
 Pass was evident (Stabeno and Reed, 1994; Stabeno et  
 al., 1999). Hence, the SLP field has indicated that

382 there was relatively strong inflow of the Alaskan  
 383 Stream and the increasing transport of the ANSC  
 384 and the BSC, leading to eddy-rich conditions along  
 385 the shelf edge in 2000. From in situ observations, the  
 386 transport in the ANSC and BSC systems (the refer-  
 387 ence level of 1500 dbar or the bottom) increased in  
 388 2000 (P.J. Stabeno, personal communication), which  
 389 corresponded to our results. Although there is no  
 390 evidence to explain the interaction among the Aleu-  
 391 tian low pressure, ANSC, and BSC, the effects of  
 392 climatic forcing on the current system around the  
 393 Bering Sea and Gulf of Alaska deserve consideration.  
 394 The relationship of the Bering Slope Current eddy  
 395 field and primary production was described using  
 396 satellite multisensor remote sensing in this study.  
 397 However, small-scale mesoscale features were ne-  
 398 glected due to limited SSHAs and chl-*a*. In future  
 399 work, we plan to conduct more high-resolution analy-  
 400 ses that take into account small eddy activity.

## 403 Acknowledgements

404 We thank Dr. Richard D. Brodeur, Dr. Phyllis J.  
 405 Stabeno, and an anonymous reviewer for their valued  
 406 and constructive comments. We are grateful for the  
 407 improvement of  $P_{opt}^B$  by Dr. Takuhiko Kameda and  
 408 Dr. Joji Ishizaka. We also thank Dr. John R. Bower for  
 409 reading through our manuscript and improving our  
 410 English. Part of this study is supported by the National  
 411 Space Development Agency of Japan (NASDA)  
 412 through the program of Arctic Research projects  
 413 using International Arctic Research Center (IARC)–  
 414 NASDA Information System (INIS) and Satellite  
 415 Data. Also this work was partly supported by Grant-in  
 416 Aid (14405026) for Science Research from the  
 417 Ministry of Education, Culture, Sports, Science, and  
 418 Technology, Japan (S.S.). We appreciate all the help  
 419 and support of the concerned research institutes,  
 420 including the University of Alaska Fairbanks and  
 421 IARC. All figures were described using the Generic  
 422 Mapping Tool (GMT) and SeaWiFS chl-*a* was  
 423 processed using SeaDAS.
